The views expressed on statistical, methodological, technical, or operational issues are those of the authors and not necessarily those of the U.S. Census Bureau, IBM, or the University of Chicago.
Various authors – Cleveland and Tiao (1976), Burridge and Wallis (1984), and Depoutot and Planas (1998) – have compared weight functions from X-11 versus model-based seasonal adjustment filters. We suggest a different approach to comparing filters by computing the mean squared error (MSE) when using an X-12-ARIMA filter for estimating the underlying seasonal component from an ARIMA model-based decomposition, and comparing this to the MSE of the optimal model-based estimator. This provides a criterion for choosing an X-12 filter for a given series (model the series and pick the X-12 filter with lowest MSE), and also provides results on how much MSE increases when using an X-12 filter rather than the optimal model-based filter. Calculations for monthly time series following the airline model with various parameter values show generally small increases in MSE for estimating the canonical seasonal component by using the best X-12 filter instead of the optimal model-based filter. The results are much less favorable to the X-12 filters with a uniform prior distribution on the white noise allocation in the seasonal model decomposition. Examinations of simulated series show that, for the canonical decomposition, automatic filter choices of the X-12-ARIMA program sometimes use shorter seasonal moving averages than are desirable.
1. INTRODUCTION

The fixed filtering approach to seasonal adjustment, as implemented in the original Census X-11 program (Shiskin et al., 1967) and its successors, X-11-ARIMA (Dagum, 1975) and X-12-ARIMA (Findley et al., 1998), has been widely used by government and industry. This approach relies on a finite set of empirically developed moving averages. The user can either specify the particular moving averages used for a time series or let the program choose them automatically according to some empirical criteria. An advantage to this approach is that it is relatively easy to use even for people with limited statistical background. A disadvantage is that the reliance on a limited set of filters raises the possibility of cases arising that are not well-handled by the available filters. Another disadvantage is that the empirical criteria used by the program to automatically select filters do not follow from standard statistical principles that would lead to certain optimality properties such as minimum mean squared error (MMSE).

In contrast, a model-based approach to seasonal adjustment specifies stochastic models for the observed series and underlying components, and derives seasonal adjustment filters from optimal signal extraction theory. The filters used are thus determined by the model form specified, by assumptions made about the component decomposition, and by estimates of the model parameters. See Bell and Hillmer (1984) for discussion. The model-based approach offers more flexibility in determining filters than the empirical filtering approach, as well as providing for determination of filters according to standard statistical principles.

To relate these two approaches, Cleveland and Tiao (1976) and Burridge and Wallis (1984) proposed stochastic models leading to seasonal adjustment filters close to linear filters used in the Census X-11 program. Chu (2000) extended this line of work further to provide models for 24 X-12 symmetric filters.¹ These results can provide a model-based foundation for use of X-12 filters. However, the models developed to approximate the X-12 filters are rather

¹ We use the term “X-12 filter” to refer to the filters available in the X-12-ARIMA program,
complex, more complex than models used in practice, making this approach rather cumbersome and vague in practice as a means of evaluating and choosing X-12 filters. Depoutot and Planas (1998) and Planas and Depoutot (2002) avoid complex approximating models by restricting consideration to the popular “airline” ARIMA model (Box and Jenkins, 1976), using the ARIMA model-based seasonal decomposition approach of Hillmer and Tiao (1982) and Burman (1980). They specifically focus on matching the weights of X-12 filters with weights from model-based optimal filters under the “canonical decomposition”.

In this paper we suggest a different approach to comparing X-12 linear filters to model-based filters. More specifically, for a given ARIMA model we compute the mean squared error (MSE) when a specific X-12 filter is used to estimate the underlying seasonal component from the model-based decomposition. This approach provides results on how much accuracy is lost (in terms of increased MSE) by using an X-12 filter rather than the optimal model-based filter. The approach also provides an objective means of choosing an X-12 filter, namely, pick the filter that minimizes the MSE.

An issue that arises in the ARIMA model-based approach concerns uncertainty about the model decomposition in regard to allocation of white noise between the seasonal and nonseasonal components. We consider two options for dealing with this uncertainty. One is to assume a particular white noise allocation, such as the canonical decomposition of Hillmer and Tiao (1982) and Burman (1980), which allocates all the white noise to the nonseasonal component. The other option considered is to allow for uncertainty about the decomposition by putting a prior distribution on the white noise allocation and examining the average MSE over the prior. Here we obtain results for both the canonical decomposition (which can be viewed as corresponding to a particular degenerate prior) and for a uniform prior over the admissible range of

though we could equally well use the term “X-11 filter,” as is done by some authors, such as Depoutot and Planas (1998). The basic filtering approach of X-12-ARIMA (and also of X-11-ARIMA) is that of the original X-11 program, and, in fact, the seasonal adjustment procedure in the X-12 program is referred to as X11. Also, most of the filters used in X-12 were available in the X-11 program, though X-12 does provide some additional choices based on a few seasonal and trend moving averages not available in X-11.
the white noise allocation. Bell and Otto (1992) also used these two cases in a Bayesian approach to treating ARIMA model-based seasonal adjustment.

We should emphasize that the comparisons in this paper reflect differences between X-12 and model-based seasonal adjustment only in regard to differences in their seasonal and seasonal adjustment linear filters. The comparisons do not reflect any differences between them in other important aspects of the process of seasonal adjustment. While this may be a limitation, it is worth noting that some other major aspects of seasonal adjustment, such as modeling and adjustment for calendar effects (trading-day and holiday effects) and outliers, are generally similar or even identical between X-12 and model-based procedures. In particular, the new X-13ARIMA-SEATS program (U.S. Census Bureau, 2012) addresses calendar effects and outliers via a common regression plus time series modeling front end used for either X-12 or model-based (SEATS) seasonal adjustment. (But note that X-12’s replacements of “extreme values” are in addition to the outlier adjustments and are not part of model-based seasonal adjustment.)

In Section 2, we briefly review the ARIMA model-based approach to seasonal adjustment and the white noise allocation issue. This sets up the framework for developing our approach to comparing X-12 and model-based filters in Section 3. Section 4 then presents results of such comparisons for a monthly time series following the airline model for various combinations of the airline model parameters. The results, which are given for symmetric filters, show which X-12 filters fare best in this comparison for series following various airline models, and how much accuracy is lost in terms of increased MSE from using the best X-12 filter instead of the optimal model-based filter. In many cases little accuracy is lost in estimating the canonical model-based seasonal component by using the best X-12 filter. The results are much less favorable to the X-12 filters when we assume a uniform prior distribution on the white noise allocation. Additional results presented in Section 4 use simulated series from the airline model to compare our best X-12 filter selections with those from the automatic filter selection procedure of the X-12-ARIMA program. Finally, Section 5 summarizes the results and raises some questions for future research.
2. THE ARIMA MODEL-BASED APPROACH AND THE WHITE NOISE ALLOCATION ISSUE

In this section, we briefly review the ARIMA model-based approach to seasonal adjustment and the white noise allocation issue. Following Hillmer and Tiao (1982) and Burman (1980), we suppose that an observable time series, $Z_t$, where in this paper $t$ denotes the month, can be decomposed as

$$Z_t = S_t + N_t,$$  \hspace{1cm} (1)

where $S_t$ and $N_t$ are unobservable seasonal and nonseasonal components that follow the ARIMA models

$$U(B)S_t = \eta_S(B)b_t, \quad \text{and}$$  \hspace{1cm} (2)

$$(1 - B)^d \phi_N(B)N_t = \eta_N(B)c_t,$$  \hspace{1cm} (3)

respectively. In (2) and (3) $B$ is the backshift operator such that $BS_t = S_{t-1}$, $U(B) = (1 + B + \cdots + B^{s-1})$, and $s$ denotes the number of time periods per year (here $s = 12$). Further, $\phi_N(B)$ is a polynomial in $B$ of degree $p$ with its zeros lying outside the unit circle, while $\eta_S(B)$ and $\eta_N(B)$ are polynomials of degrees $s - 1$ and $p + d$, respectively, with zeros lying on or outside the unit circle. (Note: These assumptions effectively impose only upper limits on the degrees. If $\eta_S(B)$ has lower degree than $s - 1$ we can append additional terms with zero coefficients to raise its degree to $s - 1$, and similarly if $\eta_N(B)$ has lower degree than $p + d$.) We also assume that $U(B)$ and $\eta_S(B)$ have no common zeros, and that $(1 - B)^d \phi_N(B)$ and $\eta_N(B)$ have no common zeros. The innovation series $b_t$ and $c_t$ are mutually independent Gaussian white noises with variances $\sigma_b^2$ and $\sigma_c^2$, respectively.

Overall model implied by component models: Let $A_Z(z)$, $A_S(z)$, and $A_N(z)$ denote the “pseudo” autocovariance generating functions (ACGFs) of $Z_t$, $S_t$, $N_t$,
and $N_t$, respectively. We then have from (1) – (3) that

$$AZ(z) = AS(z) + AN(z), \quad (4)$$

where

$$AS(z) = \frac{\eta_S(z)\eta_S(z^{-1})}{U(z)U(z^{-1})}\sigma_b^2,$$

and

$$AN(z) = \frac{\eta_N(z)\eta_N(z^{-1})}{(1-z)^d (1-z^{-1})^d \phi_N(z)\phi_N(z^{-1})}\sigma_c^2. \quad (6)$$

It follows that $AZ(z)$ can be written in the form

$$AZ(z) = \frac{\theta(z)\theta(z^{-1})}{\varphi(z)\varphi(z^{-1})}\sigma_a^2,$$

where $\varphi(z) = U(z)(1-z)^d\phi_N(z)$ and $\theta(z)$ both have degree $p + s + d - 1$. Thus, the overall model for $Z_t$ is the ARIMA model

$$\varphi(B)Z_t = \theta(B)a_t. \quad (8)$$

The innovation series $a_t$ is Gaussian white noise with variance $\sigma_a^2$. We assume that all the zeros of $\theta(B)$ are outside of the unit circle.

**Decomposition of an overall model:** On the other hand, given an overall model in the form of (8), which can be verified from observable data $Z_t$, we can proceed to use the results in Hillmer and Tiao (1982) and Burman (1980) to obtain a decomposition of $Z_t$ into seasonal and nonseasonal components $S_t$ and $N_t$ as follows.

Note first that, given the ARIMA model (8) for $Z_t$, any choice of $\eta_S(B)$, $\eta_N(B)$, $\sigma_b^2$, and $\sigma_c^2$ satisfying (4) – (7) gives what is termed an "acceptable" decomposition of $AZ(z)$ into seasonal and nonseasonal component ACGFs, corresponding to an acceptable decomposition of $Z_t$ into seasonal and nonseasonal component series as in (1). Now if $AS(z)$ and $AN(z)$ represent an
acceptable decomposition, then \( A_S(z) + \tau \) and \( A_N(z) - \tau \), where \( \tau \) is a constant, represent another acceptable decomposition provided that \( A_S(e^{-i\lambda}) + \tau \) and \( A_N(e^{-i\lambda}) - \tau \) are nonnegative for all \( \lambda \in [0, \pi] \). Thus, in general there are an infinite number of ways one can decompose a series corresponding to a given overall model.

Now we can represent the range of acceptable decompositions in terms of one unidentified parameter. Specifically, writing \( \Phi(B) = \varphi(B)/U(B) = (1 - B)^d \phi_N(B) \), and following Hillmer and Tiao (1982), we perform a (unique) partial fractions decomposition of \( A_Z(z) \) in (7) into

\[
A_Z(z) = A_S(z) + A_N(z) + \kappa,
\]

where

\[
A_S(z) = \frac{Q_S(z)}{U(z)U(z^{-1})}, \quad \text{with} \quad Q_S(z) = q_0S + \sum_{i=1}^{s-2} q_iS (z^i + z^{-i}),
\]

\[
A_N(z) = \frac{Q_N(z)}{\Phi(z)\Phi(z^{-1})}, \quad \text{with} \quad Q_N(z) = q_0N + \sum_{i=1}^{p+d-1} q_iN (z^i + z^{-i}),
\]

and \( \kappa \) is a constant. Let

\[
A_{SC}(z) = \frac{Q_S(z)}{U(z)U(z^{-1})} - \varepsilon_s, \quad \text{and}
\]

\[
A_{NC}(z) = \frac{Q_N(z)}{\Phi(z)\Phi(z^{-1})} - \varepsilon_n,
\]

where

\[
\varepsilon_s = \min_{\lambda \in [0,\pi]} \frac{Q_S(e^{-i\lambda})}{U(e^{-i\lambda})U(e^{i\lambda})}, \quad \text{and}
\]

\[
\varepsilon_n = \min_{\lambda \in [0,\pi]} \frac{Q_N(e^{-i\lambda})}{\Phi(e^{-i\lambda})\Phi(e^{i\lambda})}.
\]

Then, we can write
As shown in Hillmer and Tiao (1982), an acceptable decomposition exists if and only if \( \gamma_{\text{max}} \equiv \varepsilon_s + \varepsilon_n + \kappa \geq 0 \). When this is so, acceptable decompositions \( A_Z(z) = A_{SC}(z) + A_{NC}(z) + \varepsilon_s + \varepsilon_n + \kappa \) can be indexed by \( \gamma \in [0, \gamma_{\text{max}}] \), and the range of acceptable seasonal and nonseasonal components must correspond to

\[
A_{SC}(z) + \gamma, \quad (9) \\
A_{NC}(z) + (\gamma_{\text{max}} - \gamma). \quad (10)
\]

We shall let \( S'_\gamma \) denote the seasonal component corresponding to \( A_{SC}(z) \) and \( N'_\gamma = Z_t - S'_\gamma \) the nonseasonal component corresponding to \( A_{NC}(z) \). The constant \( \gamma_{\text{max}} \), when positive, can be viewed as corresponding to unobservable white noise in the series \( Z_t \). We see from equations (9) and (10) that the value specified for \( \gamma \in [0, \gamma_{\text{max}}] \) thus determines an allocation of this white noise between the unobserved seasonal and nonseasonal components.

**Canonical Decomposition:** In (9) it is easy to see that setting \( \gamma = 0 \) will minimize the innovation variance \( \sigma_b^2 \) of the seasonal component. Hillmer and Tiao (1982) call this the “canonical decomposition” and discuss its properties. Fundamentally, the canonical decomposition provides the most stable seasonal component, i.e., the one that shows the least variation over time from a fixed seasonal pattern. At the other extreme, setting \( \gamma = \gamma_{\text{max}} \) will maximize the innovation variance of the seasonal component and provide the most variation over time from a fixed seasonal pattern. The only information provided about \( \gamma \) by the model (8) for the observed series \( Z_t \), and hence by the data, is the range \( \gamma \in [0, \gamma_{\text{max}}] \). This means that given the ARIMA model for \( Z_t \) in (8), unobserved seasonal components for all values of \( \gamma \in [0, \gamma_{\text{max}}] \) are equally consistent with the data. Dealing with uncertainty about \( \gamma \) is discussed in Section 3.

### 3. AN APPROACH TO COMPARING X-12 AND MODEL-BASED SEASONAL FILTERS

In this section we develop an approach to comparing any given linear seasonal
filter with the optimal model-based seasonal filter based on comparing their MSEs when estimating the seasonal component $S^\gamma_t$. We then apply the results to comparing linear X-12 and optimal model-based seasonal filters. We first discuss the case where $\gamma$ is assumed to be known (Section 3.1), and then the case where $\gamma$ is unknown (Section 3.2). Although numerical results given in Section 4 consider only symmetric filters applied to doubly infinite data, the derivations given here apply to symmetric or asymmetric filters applied to either semi-infinite (data into the infinite past) or finite data.

Let $w_S(B) = \sum_i w_{Si} B^i$ be a specific linear filter to be used for estimating any seasonal component $S_t$, i.e., $\hat{S}_t = w_S(B)Z_t$, and let $w_N(B) = 1 - w_S(B)$ be the corresponding linear filter for estimating $N_t$. For a given value of $\gamma$, the error in estimating $S^\gamma_t$ by $\hat{S}_t$, which we shall denote by $g^\gamma_t = S^\gamma_t - \hat{S}_t$, is

$$g^\gamma_t = w_N(B)S^\gamma_t - w_S(B)N^\gamma_t. \tag{11}$$

Given that $S^\gamma_t$ and $N^\gamma_t$ are assumed to follow models of the form of (2) and (3), it is easy to see from (11) that the error series $g^\gamma_t$ will be stationary if $w_N(B)$ contains $U(B)$ as a factor and $w_S(B)$ contains $(1 - B)^d$ as a factor. This will be true for all the filters considered here. When this is true, the ACGF of $g^\gamma_t$ is

$$A^\gamma_s(z) = w_N(z)w_N(z^{-1}) A^\gamma_s(z) + w_S(z)w_S(z^{-1}) A^\gamma_n(z), \tag{12}$$

and the corresponding MSE is

$$\text{MS}(g^\gamma_t) = (2\pi)^{-1} \int_{-\pi}^{\pi} A^\gamma_s(e^{-i\lambda})d\lambda. \tag{13}$$

The above results were given by Pierce (1979). Since (12) shows $A^\gamma_s(z)$ to be symmetric (coefficients of $z^k$ and $z^{-k}$ are equal for all $k$), we can compute $\text{MS}(g^\gamma_t)$ by expanding (12) and taking the constant term (coefficient of $z^0$ in the expansion). Before doing so, however, we must cancel the unit root factors $U(z)U(z^{-1})$ that appear in $w_N(z)w_N(z^{-1})$ and in the denominator of $A^\gamma_s(z)$, and similarly cancel $(1 - z)^d(1 - z^{-1})^d$ that appears in $w_S(z)w_S(z^{-1})$ and in the denominator of $A^\gamma_n(z)$.
We now discuss an interesting and important property of $\text{MS}(g_i^\gamma)$. Watson (1987, eq. (3.9)) showed that (allowing for differences in notation)

$$\text{MS}(g_i^\gamma) = \text{MS}(g_i^0) + \gamma \cdot (1 - 2w_{S0}), \quad (14)$$

where $g_i^0$ is the estimation error for $S_i^\gamma$ at $\gamma = 0$, i.e., the error in estimating the canonical seasonal $S_i^0$, and $w_{S0}$ is the weight that $w_S(B)$ applies to $Z_t$ (the observation at the time point at which we are estimating $S_t$). This is the “center weight” for symmetric filters. When $w_{S0} < 0.5$ in (14), $\text{MS}(g_i^\gamma)$ is an increasing linear function of $\gamma$ that is thus bounded below by $\text{MS}(g_i^0)$ and bounded above by $\text{MS}(g_i^{\gamma_{\text{max}}})$.

Equations (12) – (14) apply whether $w_S(B)$ is a model-based or X-12 filter, symmetric or asymmetric. When $w_S(B)$ is the (symmetric or asymmetric) model-based filter corresponding to the true value of $\gamma$, we get the optimal (MMSE) signal extraction estimate, which we shall denote as $\hat{S}_i^\gamma$. In the symmetric case, the optimal signal extraction filter is $w_{S}^\gamma(B) = A_S^\gamma(B)/A_Z(B)$ and (12) simplifies to $A_S^\gamma(z) = A_N^\gamma(z)/A_Z(z)$ (Bell, 1984). Bell and Martin (2004) discuss optimal asymmetric signal extraction, and computation of the resulting MSE, with ARIMA component models.

### 3.1 Comparing X-12 and Model-Based Filters When $\gamma$ Is Known

Now let $j$ index the filters within a relevant set $J$ of X-12 linear filters, such as the symmetric X-12 seasonal filters. We write $x_S^j(B)$ for a particular X-12 seasonal filter, with corresponding estimated seasonal component $\hat{S}_i^j = x_S^j(B)Z_t$. Letting $g_i^{\gamma,j} = S_i^\gamma - \hat{S}_i^j$ be the error series, for each $j \in J$ we can expand (12) as discussed above to compute $\text{MS}[g_i^{\gamma,j}]$. We can then pick the best X-12 filter, $x_S^{j\text{opt}}(B)$, to achieve the minimum MSE, i.e.,

$$\text{MS} \left[ g_i^{\gamma,j\text{opt}} \right] = \min_{j \in J} \left\{ \text{MS} \left[ S_i^\gamma - \hat{S}_i^j \right] \right\}. \quad (15)$$

Stationarity of the error series $g_i^{\gamma,j}$ for any $\gamma$ and any symmetric X-12 filter follows from (11) since, according to Bell (2012), any symmetric X-12 seasonal filter $x_S^j(B)$ contains $(1-B)^6$ and any symmetric X-12 seasonal adjustment...
filter, \( x_N^j(B) = 1 - x_N^j(B) \), contains \( U(B) \). Asymmetric filters obtained by applying symmetric X-12 filters to series extended by a sufficient number of forecasts and backcasts from the ARIMA model (8) will also contain the needed differencing operators.

We remark here that the center weight for all the symmetric X-12 seasonal filters satisfies the condition \( w_{S0}^0 < 0.5 \). (Note, e.g., Bell and Monsell, 1992.) Hence, for X-12 symmetric seasonal filters, the minimum of \( \text{MS}(g_{t,y}) \) as a function of \( \gamma \) always occurs at \( \gamma = 0 \), i.e., at the canonical decomposition. Thus, any X-12 symmetric seasonal filter will better estimate the canonical seasonal component for a given model than any other admissible seasonal component for that model.

### 3.2 Comparing X-12 and Model-Based Filters When \( \gamma \) Is Unknown

When the value of \( \gamma \) in the model-based decomposition is regarded as unknown, we assign to \( \gamma \) a prior probability density, \( p(\gamma) \), over the acceptable range \([0, \gamma_{\text{max}}]\), and then compute, for a given filter, the average MSE over \( p(\gamma) \). That is, we compute \( E_{\gamma} \text{MS}(g_{t,y}) = \int \text{MS}(g_{t,y}) p(\gamma) d\gamma \). Computation of this average MSE is greatly aided by the linearity of \( \text{MS}(g_{t,y}) \) in \( \gamma \) as shown in (14). We thus have the following lemma.

**Lemma** Let \( Z_t = S_t^\gamma + N_t^\gamma \) be an acceptable decomposition of \( Z_t \) following the model (8), where \( S_t^\gamma \) and \( N_t^\gamma \) follow models given by (2) and (3) corresponding to ACGFs as given by (5) and (6). Let \( w_S(B) \) be a linear seasonal filter such that the error series \( g_{t,y} \) in (11) is stationary. Then, the average MSE over the distribution of \( \gamma \) with density \( p(\gamma) \) for estimating \( S_t^\gamma \) by \( w_S(B)Z_t \) is

\[
E_{\gamma} \text{MS} \left( g_{t,y} \right) = \text{MS} \left( g_{t,\mu_\gamma} \right),
\]

where \( \mu_\gamma = \int \gamma p(\gamma) d\gamma \) is the mean of \( \gamma \).

**Proof** The result follows immediately from (14) by noting that

\[
E_{\gamma} \text{MS} \left( g_{t,y} \right) = \text{MS} \left( g_{t,0} \right) + \mu_\gamma \left( 1 - 2w_{S0} \right) = \text{MS} \left( g_{t,\mu_\gamma} \right).
\]
Note In the special case of a uniform prior for $\gamma$, $\mu_\gamma = (1/2)\gamma_{\text{max}}$. The Lemma also applies to the canonical decomposition by setting $\mu_\gamma = 0$, since the canonical decomposition can be viewed as corresponding to a degenerate prior of $\gamma = 0$ with probability one.

Note that $w_S(B)$ could be either a symmetric filter or an asymmetric filter, so the Lemma applies to both symmetric and concurrent season adjustment. It could also be either a finite or an infinite filter. The only requirements are that (i) $w_S(B)$ and $w_N(B)$ contain the needed operators $(1 - B)^d$ and $U(B)$, respectively, so the error series $g_t^\gamma$ is stationary, and (ii) the time point for which we are estimating $S_t^\gamma$ lies within the span of the observed data. The second requirement excludes forecasting of $S_t^\gamma$, since, for forecasting, $w_N(B) \neq 1 - w_S(B)$.

The Lemma can be used to compute the average MSE for a given filter, X-12 or model-based, and in each case we need only compute the MSE when the filter is used to estimate $S_t^{\mu_\gamma}$. Given a set $J$ of X-12 filters, the best X-12 filter in terms of average MSE is thus the one that achieves the minimum average MSE over the set. For related results and further insights, see Watson (1987) and Bell and Otto (1992).

3.3 MSE Comparison Measures

In Section 4 we compare average (over $p(\gamma)$) MSEs of symmetric X-12 and optimal model-based filters. We do this both for the canonical decomposition ($\gamma = 0$) and for the case of unknown $\gamma$ following a uniform prior on $[0, \gamma_{\text{max}}]$. From the previous Lemma, these average MSEs are just the MSEs for estimating $S_t^{\mu_\gamma}$, with $\mu_\gamma = 0$ for the canonical decomposition, and $\mu_\gamma = \gamma_{\text{max}}/2$ for the uniform prior on $\gamma$.

We present the average MSE comparisons as percentage differences, using the average MSE for the best model-based estimator, $\tilde{S}_t^{\mu_\gamma} = w_S^{\mu_\gamma}(B)Z_t$, as a base value. So the percentage difference for a given X-12 filter $x_S^\gamma(B)$ is

$$100 \times \left\{ \frac{\text{MS} \left[ S_t^{\mu_\gamma} - x_S^\gamma(B)Z_t \right] - \text{MS} \left[ S_t^{\mu_\gamma} - \tilde{S}_t^{\mu_\gamma} \right]}{\text{MS} \left[ S_t^{\mu_\gamma} - \tilde{S}_t^{\mu_\gamma} \right]} \right\}.$$  

(16)
When \( x_j^j(B) \) in (16) is \( x_j^j(B) \) satisfying (15) (with the \( \gamma \) in (15) fixed at \( \mu_\gamma \)), then (16) gives the percentage increase in MSE from using the best X-12 filter instead of the best model-based filter for estimating \( S^j_{\mu_\gamma} \).

The denominator of (16) can be computed from standard signal extraction results. In the numerator we can write

\[
S^j_{\mu_\gamma} - x_j^j(B)Z_t = \left[ S^j_{\mu_\gamma} - \tilde{S}^j_{\mu_\gamma} \right] + \left( w^j_{\mu_\gamma}(B) - x_j^j(B) \right) Z_t. \tag{17}
\]

The first term on the right hand side of (17), the error in the optimal estimate \( \tilde{S}^j_{\mu_\gamma} \), is orthogonal to all linear functions of \( Z_t \). Thus, the two terms in (17) are orthogonal and the numerator of (16) immediately reduces to \( \text{MS} \left[ (w^j_{\mu_\gamma}(B) - x_j^j(B))Z_t \right] \), the MS of the difference of the two estimators \( \tilde{S}^j_{\mu_\gamma} \) and \( x_j^j(B)Z_t \).

For the airline model, which we use here, \( w^j_{\mu_\gamma}(B) - x_j^j(B) \) always contains \( U(B)(1 - B)^2 = (1 - B)(1 - B^s) \), so that \( (w^j_{\mu_\gamma}(B) - x_j^j(B))Z_t \) is stationary. Thus, the ACGF of \( (w^j_{\mu_\gamma}(B) - x_j^j(B))Z_t \), and hence its MS, can be calculated.

Use of (16) thus implies that, apart from the normalization by the denominator, we measure the distance between the X-12 and model-based filters by comparing the mean squared difference of their seasonal component estimators. In contrast, Depoutot and Planas (1998), hereafter DP, directly compared filter weights from X-12 and (canonical) model-based filters. Their criterion for comparing an X-12 filter, \( x_j^j(B) \), with a canonical model-based filter, \( w^0_{S}(B) \), can be written

\[
\sum_h \left( w^0_{S,h} - x_j^j_{S,h} \right)^2 = (2\pi)^{-1} \int_{-\pi}^{\pi} \left| w^0_{S} \left( e^{-i\lambda} \right) - x_j^j \left( e^{-i\lambda} \right) \right|^2 d\lambda. \tag{18}
\]

Equation (18) can be thought of as measuring the mean squared difference of two “seasonal component estimators” obtained by applying the X-12 and canonical model-based filters to a white noise series (with variance 1). Our criterion measures the mean squared difference of the two estimators of the canonical seasonal component of the series \( Z_t \). This can be written as

\[
\text{MS} \left[ \left( w^0_{S}(B) - x_j^j(B) \right) Z_t \right] = \int_{-\pi}^{\pi} \left| w^0_{S} \left( e^{-i\lambda} \right) - x_j^j \left( e^{-i\lambda} \right) \right|^2 f(\lambda) d\lambda, \tag{19}
\]
where \( f(\lambda) = (2\pi)^{-1} A_Z(e^{-i\lambda}) \) is the spectral density of \( Z_t \). This weights the squared difference of the X-12 and canonical model-based filters at each frequency \( \lambda \) by the value of the spectral density \( f(\lambda) \) at that frequency.\(^2\) Finally, despite the difference between (18) and (19), DP’s choices of seasonal moving averages (for symmetric filters and the canonical decomposition), are essentially in agreement with those that we report in the next section. Note that our focus here is not just on the best X-12 filter choices, though, but also on the MSEs related to the X-12 filters, and particularly on how these compare, via (16), to the MSEs of the model-based filters.

## 4. COMPARING X-12 AND MODEL-BASED SYMMETRIC FILTERS

In this section we apply the results of Section 3 to the airline model with various parameter values for monthly time series \( Z_t \),

\[
(1 - B)(1 - B^{12}) Z_t = (1 - \theta_1 B)(1 - \theta_{12} B^{12}) a_t, \tag{20}
\]

where \( a_t \) is a normally distributed white noise series with variance that we set to unity. Our first objectives are to (i) compare the average MSEs for various X-12 filters to the average MSE of the optimal model-based filter, and (ii) determine which of a set of \( J \) X-12 seasonal filters minimizes the average MSE, \( \text{MS}[g_t^{\mu, \gamma, j}] \).

We then examine, for given airline models, how much the MSE is increased by using the best of the X-12 filters instead of the optimal model-based filter. We focus on the cases of the canonical decomposition (\( \mu_\gamma = 0 \)) and the uniform prior on \( \gamma (\mu_\gamma = \gamma_{\text{max}}/2) \).

We study the airline model (20) because it is probably the most commonly used model for analyzing seasonal time series. We restrict consideration to nonnegative values of \( \theta_1 \) and \( \theta_{12} \). One reason for this is that the condition

\(^2\) DP write their comparison criterion as \( \pi^{-1} \int_0^\pi \left| w_0^j(e^{-i\lambda}) - x^j_0(e^{-i\lambda}) \right|^2 \text{d}\lambda \), a form that is equivalent to (18) for symmetric filters but not for asymmetric filters. They also start with \( \text{d}\lambda \) replaced by \( \text{d}m(\lambda) \), where \( m(\lambda) \) is a general measure on \([0, \pi]\), though they explicitly consider only Lebesgue measure, i.e., \( \text{d}\lambda \). Note that setting \( \text{d}m(\lambda) = f(\lambda)\text{d}\lambda \) yields our criterion (19).
\( \theta_{12} \geq 0 \) is needed for an acceptable decomposition to exist (Hillmer and Tiao (1982), p. 67). A second reason is that, in practice, estimated models tend to satisfy these constraints. DP modeled over 7,000 series with the airline model and found that about 97 percent of the estimates of the model parameters (\( \theta_1 \), \( \theta_{12} \)) were positive.

The symmetric X-12 filters are determined by the choices of seasonal and trend moving averages (MAs) that are applied in X-12’s iterative filtering calculations. See Bell and Monsell (1992), Findley et al. (1998), or Chu (2000) for details. As notation for the X-12 filters we write, for example, S3335H13 to denote the X-12 seasonal filter that results when the first seasonal MA is the 3 × 3 \((1/9)(F_{12}^{12} + 1 + B_{12}^{12})(F_{12}^{12} + 1 + B_{12}^{12})\), the second seasonal MA is the 3 × 5 \((1/15)(F_{12}^{12} + 1 + B_{12}^{12})(F_{24}^{24} + F_{12}^{12} + 1 + B_{12}^{12} + B_{24}^{24})\), and the trend MA is the 13-term symmetric Henderson MA. Findley et al. (1998, pp. 149–151) and Dagum (1985, p. 634) discuss the Henderson trend MAs.

For the set \( J \) of X-12 symmetric seasonal filters that we consider here it would be desirable, in principle, to include all the possibilities, i.e., those resulting from all possible combinations of X-12’s seasonal and trend MAs. This would involve, however, a large number of combinations, and would include several sets of filters not appreciably different from one another. (For example, Bell and Monsell (1992) note that filters with S3335 versus S3535, and having the same Henderson trend MA, are not appreciably different.) We thus restrict \( J \) to contain the 20 X-12 seasonal filters generated from the combinations of five different seasonal MAs (S3131, S3333, S3335, S3339, and S315315) and 4 Henderson trend MAs (H9, H13, H17, and H23). As will be noted in Section 4.3, the S3333, S3335, and S3339 seasonal MAs, as well as the H9, H13, and H23 Henderson trend MAs, are possibilities that can arise from the X-12-ARIMA automatic filter selection scheme. The S3131 and S315315 seasonal MAs, and the H17 Henderson trend MA, are available as user-specified options.\(^3\)

\(^3\) There are two minor differences in X-12-ARIMA between automatic selection of a given seasonal MA and user specification of the same MA. First, automatic selection applies only to the second seasonal MA in the X-11 filtering; the first seasonal MA under automatic selection is always the 3 × 3. User specification, in contrast, applies to both seasonal MAs. Thus, automatic selection of the 3 × 5 seasonal MA implies, in our notation, the S3335 filter, whereas user specification of the 3 × 5 seasonal MA implies S3535. As just noted, these two filters are quite close. The second minor difference is that automatic selection affects only the final iteration
Section 4.1 following gives MSE comparisons between X-12 and model-based symmetric filters for the canonical decomposition, while Section 4.2 gives MSE comparisons for the case of the uniform prior on $\gamma$. MSEs for the symmetric model-based filters were computed from standard signal extraction results (Bell, 1984), while those for the symmetric X-12 filters were computed by expanding (12) as discussed in the first part of Section 3. Section 4.3 examines automatic X-12 filter selections for time series simulated from the airline model and notes how these selections compare to the “best selections” as determined in Sections 4.1 and 4.2. One point to note for practical application of the results in this section is that there is an implicit assumption that the time series under consideration is “sufficiently long” for the filters being compared. That is, we implicitly assume the series is long enough and the filter weights die out sufficiently quickly as they reach forward and backward through the series so that the weights that would be applied before the beginning and after the end of the observed series are essentially negligible.

4.1 Comparisons for the Canonical Decomposition

We consider first the case where the true seasonal component is from the canonical decomposition ($\gamma = 0$) of the airline model. Table 1 below shows the best X-12 filter, the minimum MSE in (15), and the best X-12 filter’s MSE percentage difference (16) for the combinations where the parameter $\theta_1$ takes one of the values \{0.9, 0.7, 0.5, 0.3, 0.1\} and the parameter $\theta_{12}$ takes one of the values \{0.9, 0.8, 0.7, 0.6, 0.5, 0.4, 0.3, 0.2, 0.1\}. We use fewer values of $\theta_1$ because the variation in the results across different $\theta_1$ values is not that large. We note the following from the results in the table:

1. The percentage increase in MSE from using the best X-12 symmetric filter rather than the optimal model-based filter is generally small for estimating the canonical seasonal. It is generally less than or equal to about 12 percent, except for large values of $\theta_{12}$ (0.9) or small values of $\theta_{12}$ (0.1, 0.2).

(D) of the X-11 procedure, while user specification also determines the filters used in iterations B and C (Ladiray and Quenneville, 2001). The B and C iterations are for preliminary and final estimation (by the X-11 procedure, not via the modeling capabilities in X-12) of calendar effects and extreme values. Our focus here is on the final seasonal filtering at iteration D.

</tbody>
</table>

2. Larger values of $\theta_{12}$ imply longer seasonal MAs for the best X-12 filter. This is, of course, to be expected, because as $\theta_{12}$ approaches 1 the stochastic seasonal component will tend to become deterministic. Table 2 roughly summarizes the best seasonal MA choices corresponding to given values of $\theta_{12}$. Exceptions to these choices occur for $(\theta_1, \theta_{12}) = (0.9, 0.2), (0.7, 0.2)$, and $(0.9, 0.5)$, for which the S3333 seasonal MA is best. Figure 1 discussed below shows, though, that in cases like these, the MSEs with the seasonal MAs shown in Table 2 are only slightly higher. (As noted earlier, DP arrived at essentially these same choices of seasonal MAs.)

3. With one exception the Henderson trend MA chosen is the 9-term for $\theta_{12} \geq 0.6$ and the 23-term for $\theta_{12} \leq 0.5$. The one exception is that the 9-term Henderson is chosen for $(\theta_1, \theta_{12}) = (0.9, 0.5)$. Figure 1 shows, though, generally little dependence of the MSEs on the choice of Henderson trend MA.

4. We see that the value of $\theta_1$ has little effect on the choice of seasonal or trend MA for determining the best X-12 filter for estimating the canonical seasonal. More effect from the value of $\theta_1$ would be expected for estimation of the canonical trend component.

5. The X-12 MSEs tend to increase as $\theta_{12}$ decreases. As $\theta_1$ increases from 0.1, the MSEs first decrease and then increase, with the minimum value in each column of the table occurring at $\theta_1 = 0.5$. The largest MSE shown in Table 1 (0.220763) is about five times the smallest (0.043036).

The general conclusion from Table 1 is that, except for the largest and smallest values of $\theta_{12}$, little is lost by using the best X-12 symmetric filter in-
Figure 1  The MSEs when using various X-12 symmetric seasonal filters to estimate the seasonal component of the airline model with various parameter values ((a) canonical decomposition, (b) uniform prior on $\gamma$)
instead of the optimal model-based symmetric filter for estimating the canonical seasonal from a series that follows the airline model.

Figure 1 shows how the MSE of the X-12 estimated seasonal varies across different X-12 filters. The figure consists of two columns with three plots each. The first column of plots shows results for the canonical decomposition, and the second column of plots, to be discussed later in Section 4.2, shows results for the uniform prior on $\gamma$. The three rows of plots correspond to the values $\theta_{12} = 0.8, 0.5, \text{and } 0.2$, respectively. We use these three values to generically represent high, medium, and low values of $\theta_{12}$. Within each plot are sets of results for $\theta_1$ values 0.8, 0.5, and 0.2, as indicated. For each $\theta_1$ value the MSEs as plotted are seen to fall into five groups of four values, each group corresponding to a particular choice of X-12 seasonal MA (S3131, S3333, S3335, S3339, and S315315). The four values within each group correspond to the four choices of Henderson trend MAs considered (9-term, 13-term, 17-term, and 23-term, in that order). Two general results are evident from the plots of Figure 1 for the canonical decomposition:

- MSEs are generally insensitive to the choice of Henderson trend MA. Some exceptions occur when a very poor choice is made for the seasonal MA (e.g., with the S3131 seasonal MA when $\theta_{12} = 0.8$). Keep in mind that these results are for estimation of the canonical seasonal (equivalently, the canonical nonseasonal). We would expect more sensitivity to the choice of Henderson trend MAs in MSEs for X-12 trend estimates.

- Choice of the best seasonal MA is not crucial. For $\theta_{12} = 0.8$ the S3339 seasonal MA does about as well as the S315315, for $\theta_{12} = 0.5$ the S3333 does about as well as the S3335, and for $\theta_{12} = 0.2$ the S3333 does about as well as the S3131. Straying further than this from the best choice of seasonal MA entails a more substantial increase in MSE.

4.2 Comparisons for the Uniform Prior on $\gamma$

We now consider the case where $\gamma$ is unknown and with a uniform prior distribution over $[0, \gamma_{\text{max}}]$. From the Lemma of Section 3.2, the average MSEs,
for both the X-12 and model-based filters, are the MSEs of the filters for estimating $S_i^{\mu \gamma}$. With the uniform prior, or indeed with any symmetric prior for $\gamma$ in $[0, \gamma_{\text{max}}]$, $\mu_\gamma = \gamma_{\text{max}}/2$. Table 3 gives MSE results analogous to those in Table 1 except that we include more $\theta_1$ values, \{0.9, 0.7, 0.6, 0.5, 0.4, 0.3, 0.1\}, because the results here depend more on $\theta_1$. Comparing the results of Table 3 with those of Table 1, we observe the following:

1. The average MSE values in Table 3 are higher than the corresponding values in Table 1, as are the percentage increases. In particular, for large values of $\theta_{12}$ the MSEs are much higher, while for small values of $\theta_{12}$ the percentage increases are much larger. The higher MSEs in Table 3 could be expected due to the result noted at the end of Section 3.1 that for X-12 filters the MSE in estimating $S_i^{\mu \gamma}$ is an increasing function of $\gamma$.

2. Much shorter seasonal MAs are chosen as best X-12 filters in comparison to the choices in Table 1: the S3333 seasonal MA is generally best for $\theta_{12} \geq 0.3$, and the S3131 seasonal MA is generally best for $\theta_{12} \leq 0.2$. Exceptions are that the S3333 seasonal MA is chosen for $(\theta_1, \theta_{12}) = (0.9, 0.2)$ and $(0.7, 0.2)$, the S315315 for $(0.3, 0.9)$ and $(0.1, 0.9)$, and the S3339 for $(0.1, 0.8)$. Apart from the cases where the S315315 and the S3339 seasonal MAs are chosen, we see that for estimating the seasonal component $S_i^{\mu \gamma}$ with $\mu_\gamma = \gamma_{\text{max}}/2$ (which contains half the available white noise), short X-12 seasonal MAs are generally the best.

3. There is more variation in the best choice of Henderson trend MA in Table 3 than in Table 1. For $\theta_{12} \leq 0.5$ the 23-term is always chosen, but for $\theta_{12} \geq 0.6$ the Henderson trend MA chosen ranges from the 9-term to 23-term as $\theta_1$ increases from 0.1 to 0.9. Figure 1 shows, though, that for a given seasonal MA the MSEs for estimating $S_i^{\mu \gamma}$ with an X-12 filter over the different choices of Henderson trend MAs usually don’t vary much.

4. Contrary to the results of Table 1, in Table 3 the X-12 filter MSEs generally increase consistently as $\theta_{12}$ increases, except for $\theta_1 = 0.1$ or 0.3.

The second column of 3 plots in Figure 1 shows how the MSEs under the uniform prior on $\gamma$ vary across alternative X-12 seasonal filters. As with the
Table 3  Symmetric Filter Estimation of the Seasonal Component for the Airline Model with a Uniform Prior on $\gamma$

(Choices of the best symmetric X-12 filters, their MSE values, and the percentage increases in MSE over those of the optimal model-based filters)

Note: In each cell, 1st row: the chosen X-12 filter, i.e., $j^*$ as defined by eq. (15); 2nd row: the MMSE value from eq. (15) when $t$ is in the middle of a sufficiently long series; 3rd row: the percentage increase in MSE (X-12 filter compared to optimal model-based filter) from eq. (16).
canonical decomposition, for a given seasonal MA the MSEs usually don’t vary much over the different choices of Henderson trend MAs, except in a few cases where the seasonal MA is badly chosen. Results on the MSEs with alternative choices of the seasonal MAs are more mixed. For $\theta_{12} = 0.8$ and $\theta_1 = 0.2$, MSEs for seasonal MA choices other than the S3131 are not very different, but for $\theta_1 = 0.5$ or 0.8 (especially) more is lost by not choosing the best seasonal MA (S3333). For $\theta_{12} = 0.5$ and $\theta_1 = 0.5$ or 0.2, MSEs with the S3131, S3333, and S3335 seasonal MAs are similar, but with other seasonal MAs the MSEs are higher. For $\theta_{12} = 0.5$ and $\theta_1 = 0.8$, the MSEs with the S3333 seasonal MA are lower than those with the S3131 and much lower than the MSEs with other seasonal MAs. Finally, for $\theta_{12} = 0.2$ and any value of $\theta_1$, the MSEs with the S3131 and S3333 seasonal MAs are similar while the MSEs with the other seasonal MAs are higher.

4.3 Comparisons to X-12-ARIMA Automatic Filter Selections

In this section we compare the previous results on the “best” X-12 filter selections to automatic filter selections that are made by the X-12-ARIMA program (when the user does not select a specific filter). According to the X-12-ARIMA reference manual (U.S. Census Bureau, 2002), a $3 \times 3$ MA is used to calculate the initial seasonal estimate, then the program chooses whether to use a $3 \times 3$, $3 \times 5$, or $3 \times 9$ seasonal MA based on the size of the “moving seasonality ratio”. In our notation, either the S3333, S3335, or S3339 will be selected for the X-12 seasonal MA. Also, for monthly series, either a 9-, 13-, or 23-term Henderson trend MA will be selected based on the size of the $\bar{I}/\bar{C}$ ratio, where $\bar{I}$ and $\bar{C}$ are the average absolute month-to-month changes (percent changes for a multiplicative decomposition) of the estimated irregular and trend-cycle components, respectively. In our notation, either H9, H13, or H23 will be selected for the X-12 Henderson trend MA. For further discussion of the automatic filter selection procedure, see Ladiray and Quenneville (2001).

To examine the automatic filter selection procedure, we simulated 100 time series of length 660 from the airline model with $N(0, 1)$ innovations for each of various $(\theta_1, \theta_{12})$ combinations. We used long time series so that symmetric filters are effectively applied in the middle of the time series. We list the
Table 4  Selections of Seasonal MAs for Series Following the Airline Model:

(I) from the X-12-ARIMA automatic filter selection procedure applied to 100 simulated series;

(II) the choices that minimize the MSE as in eq. (15) for either the canonical decomposition or the uniform prior on \( \gamma \)

(II) Canonical‡: S315315 S3939 S3335 S3333 S3131

Uniform‡: S3333 \(\rightarrow\) S315315 S3333 \(\rightarrow\) S3939 S3333 S3333 S3131

Note: † The values in parentheses are the proportions of times over the 100 simulated series that the given seasonal MA was chosen.

‡ Canonical means canonical decomposition; Uniform means uniform prior on \( \gamma \).

Relative frequency of the seasonal MAs from the automatic selection procedure in the top panel, (I), of Table 4 for comparison to the best X-12 filters listed in panel (II). The latter are obtained from Table 1 for the canonical decomposition and from Table 3 for the uniform prior on \( \gamma \). The values in parentheses are the proportions of times the various filters were selected over the 100 simulated series. To simplify the table, only the selections for \( \theta_1 \) and \( \theta_{12} \) taking on the values (0.9, 0.7, 0.5, 0.3, 0.1) are listed. Selections of the Henderson trend MAs were also examined, but as Figure 1 shows that these choices rarely have much effect on the MSE, these results are not shown.

For estimating the canonical seasonal, Table 4 shows that for \( \theta_{12} = 0.7 \)
or 0.9 the automatic selection procedure tended to select seasonal MAs which are shorter than optimal. For $\theta_{12} = 0.9$ the automatic selection procedure mostly selected the S3335, and occasionally selected the S3339, instead of the best choice S315315, a choice not considered by the automatic selection procedure. For $\theta_{12} = 0.7$ the automatic selection procedure almost always selected the S3335 instead of the best choice S3339. In Figure 1, for $\theta_{12} = 0.8$ we see that selecting the S3339 instead of the S315315 seasonal MA doesn’t increase the MSE very much, but selecting the S3335 instead of the S315315 or S3339 does significantly worse. For $\theta_{12} \leq 0.5$ the automatic selection procedure tends to do a better job of selecting the seasonal MA, and Figure 1 shows in these cases that even when the best X-12 filter is not chosen the automatic selection procedure generally chooses one with only a slightly higher MSE.

For the uniform prior on $\gamma$ (equivalently, for estimating $\delta^\mu_\gamma$), Table 4 shows that the automatic selection procedure tends to select longer seasonal MAs than the best choices, though Figure 1 shows that sometimes these choices do not increase the MSEs very much. In particular, for $\theta_{12} = 0.8$ or 0.5 the automatic procedure’s usual choice of the S3335 does poorly for $\theta_1 = 0.8$, but not as badly for $\theta_1 = 0.5$ or 0.2. For $\theta_{12} = 0.5$ and low values of $\theta_1$, the automatic selection procedure frequently makes the best choice of S3333. For $\theta_{12} = 0.2$, the automatic selection procedure’s usual choice of S3333 generally does well, with only slightly higher MSE than the best choice of S3131, a choice not considered by the automatic selection procedure.

To summarize these results, under either the canonical or uniform priors the automatic filter selection procedure tends to make better choices for small than for large values of $\theta_{12}$. For $\theta_{12} \geq 0.7$, X-12-ARIMA tends to pick seasonal MAs shorter than the best for estimating the canonical seasonal, and longer than the best for estimating under the uniform prior for $\gamma$. We must also keep in mind, though, that under the uniform prior even the best X-12 filter choices usually do not do very well. Thus, the best case for the automatic selection procedure’s filter choices appears to be estimating the canonical seasonal with a value of $\theta_{12} \leq 0.5$. One qualification to note is that these results were obtained for time series sufficiently long (660 months) that results for the symmetric X-12 and model-based filters are relevant. It is possible that use of shorter seasonal MAs may do relatively better for estimating the canonical seasonal
with time series of shorter lengths more typically encountered in practice (e.g., 10–25 years), even for large values of $\theta_{12}$. Study of this question is a topic for future research.

5. CONCLUSIONS AND TOPICS FOR FUTURE RESEARCH

In this paper we examined the performance of X-12 symmetric filters for estimating the seasonal component of a model-based decomposition of a time series following the airline model. The performance was assessed in terms of average MSE for estimating the seasonal component, with these average MSES compared to those of the optimal model-based filters. The average MSE was computed over a prior distribution for the parameter $\gamma$ that allocates white noise between the seasonal and nonseasonal components of the model-based decomposition. We considered two priors for $\gamma$: the canonical decomposition (a degenerate prior on the minimum value of 0 for $\gamma$), and a uniform prior over the admissible range $[0, \gamma_{\text{max}}]$ of $\gamma$. A Lemma showed that the average MSE over the prior for $\gamma$ equals the MSE for estimating the seasonal component, $S^*_\gamma$, corresponding to setting $\gamma$ equal to its prior mean. For the canonical decomposition the prior mean is just the minimum value 0; for the uniform prior the mean is $\mu_\gamma = \gamma_{\text{max}}/2$.

As a criterion for picking an X-12 filter from among the various possible options, we suggested picking the X-12 filter that minimizes the average MSE for estimating $S^*_\gamma$, i.e., the X-12 filter that minimizes the MSE for estimating $S^*_{\mu\gamma}$. Results showed that increases in MSE from using the best X-12 symmetric filter rather than the optimal model-based symmetric filter are mostly small for the canonical decomposition. Table 2 provided results relating the best choices of seasonal MAs to values of the seasonal moving average parameter $\theta_{12}$ for the airline model. For the uniform prior on $\gamma$ the MSE increases from using the best X-12 filter are much larger.

MSE results for X-12 filters other than the best choices were mixed. Choice of the Henderson trend MA rarely had an appreciable effect on the MSE. Typically, choice of one of the seasonal MAs “close to” the best did not appreciably
increase the MSE, but choice of other seasonal MAs could lead to more substantial MSE increases.

An experiment with time series simulated from the airline model with various parameter values revealed that automatic filter choices made by the X-12-ARIMA program tended to yield the best or close to the best choices of X-12 filters for estimating the canonical seasonal from models with values of $\theta_{12} \leq 0.5$. For $\theta_{12} > 0.5$ the X-12 automatic filter choices tended to use shorter seasonal MAs than were best for estimating the canonical seasonal. Under the uniform prior even the best X-12 filters don’t do very well, so it appears that X-12-ARIMA with its automatic filter choices fares best for estimating the canonical seasonal when $\theta_{12} \leq 0.5$.

The results presented here considered only use of symmetric filters in the middle of time series sufficiently long for these filters to apply without forecast and backcast extension of the series. In Bell et al. (2012) we presented, for the canonical decomposition, analogous MSE results for concurrent adjustment and for finite sample seasonal adjustment of series with lengths from eight to forty years. Those results show, as expected, MSE increases for both X-12 and model-based filters compared to the MSEs for symmetric filters (those shown for X-12 here in Table 1). However, the percentage increases in MSEs for X-12 compared to model-based adjustment for the concurrent and finite filters are either about the same or substantially less than those presented here in Table 1 for symmetric filters. In fact, with rare exceptions (such as symmetric finite filters applied to series of forty years with a large $\theta_{12}$ value such as 0.9), we judged the MSE increases for X-12 concurrent and finite sample seasonal adjustments over the corresponding canonical model-based adjustments to be negligible. We thus concluded that, “··· in real situations that are something like those considered [there] — series of reasonable length approximately following an airline model — if a suitable choice is made of an X-12 filter, the difference in statistical accuracy between its use versus using [canonical] model-based seasonal adjustment may well be negligible”.

Several questions remain for future research. One concerns whether similar results to those shown here would be obtained with different models than the airline model? The results here suggest that for other seasonal ARIMA models the value of the seasonal moving average parameter $\theta_{12}$ would be an important determining factor in the results. Another question concerns the accuracy
of X-12 trend estimates. The approach presented here extends in a straightforward fashion to estimation of the trend component. Results of DP suggest that MSEs for X-12 trend filters would depend on the choices of both the Henderson trend MAs and the seasonal MAs.

摘 要

許多文獻如 Cleveland and Tiao (1976), Burridge and Wallis (1984), 和 Depoutot and Planas (1998) 已比較 X-11 和以模型基礎推導的季節調整濾器的權數函數, 本文則建議另一個以計算均方誤差為準則的比較方法。對於一個 ARIMA 模型所產生的時間數列, 本文分別計算以 X12-ARIMA 估計的季節成分, 及以模型為基礎所估算最適的季節成分, 並比較兩者的均方誤差。以挑選較低均方誤差為圭臬, 本文的方法提供了如何選擇最佳 X-12 季節調整濾器的準則, 以及尚可改進的幅度。當以航空公司月資料模型做模擬實驗, 我們發現如果估計標準季節成分, 選擇最佳 X-12 季節調整濾器只會造成些許均方誤差值的增加; 但如果是在白噪音為均一先驗分配假設下估計季節成分, 最佳 X-12 季節調整濾器會造成均方誤差值大幅的增加, 所以並不是一個好的選擇。模擬實驗分析發現 X-12-ARIMA 程式經常會選擇較短的季節調整濾器。
