Matrix Formulas for Nonstationary ARIMA Signal Extraction

Tucker McElroy
U.S. Census Bureau

Abstract

The paper provides general matrix formulas for minimum mean squared error signal extraction, for a finitely sampled time series whose signal and noise components are nonstationary ARIMA processes. These formulas are quite practical; as well as being simple to implement on a computer, they make it possible to easily derive important general properties of the signal extraction filters. We also extend these formulas to estimates of future values of the unobserved signal, and show how this result combines signal extraction and forecasting.

Keywords. ARIMA model, forecasting, linear filter, nonstationary time series, seasonal adjustment.

1 Introduction

We consider signal extraction for finitely-sampled nonstationary time series data that can be transformed to a mean zero, covariance stationary process by differencing operators. We suppose that the signal and noise components are nonstationary, and that differencing operators exist which transform the signal and noise components into weakly stationary time series. Signal extraction for infinitely large samples of such series has a long history, including Hannan (1967), Sobel (1967), Cleveland and Tiao (1976), Bell (1984), and Bell and Martin (2004). The unpublished report Bell and Hillmer (1988) – whose basic results are summarized in Bell (2004) – treats the finite sample case, presenting matrix formulas for the mean square optimal time-varying filters. One drawback of Bell and Hillmer’s approach is its need for the separate estimation of initial values of nonstationary signal and noise components, resulting in formulas that are awkward to implement. Pollock (2001) also relies upon estimation of these initial values (and assumes that the noise component is stationary). McElroy and Sutcliffe (2006) furnishes an improvement over the Bell and Hillmer (1988) formulas, but only for a specific type of unobserved components model. Assuming that the signal extraction problem is formulated as ARIMA signal plus ARIMA noise (we later describe how a multiple unobserved ARIMA components model can be recast into a two-component model), we show in this paper an especially simple formula that does not involve the estimation of initial values. This novel result is the main content of the paper at hand. This and other formulas discussed
below are quite practical, in that they can be used to derive important general properties of the filters, while also being simple to implement on a computer.

In the context of finite sample model-based signal extraction, one popular approach – that utilized in SEATS (see the TSW Manual by Maravall and Caparello (2004) available at www.bde.es) – has been to apply the bi-infinite filters of Bell (1984) (which are the generalizations of the Wiener-Kolmogorov signal extraction filters to the nonstationary case) to the finite sample extended with infinitely many forecasts and backcasts. The result can be calculated exactly with the aid of an algorithm of Tunnicliffe-Wilson (see Burman, 1980). While being easy to implement, this method does not readily reveal properties of finite sample filters. Moreover, it cannot produce correct finite-sample Mean Squared Errors (MSEs) for the signal estimates. Another approach is to construct the signal plus noise model in State Space Form (Durbin and Koopman, 2001) and apply the appropriate state space smoother (Kailath, Sayed, and Hassibi, 2000) to extract the signal. Efficient algorithms exist to obtain the time-varying signal extraction filters from the state space smoother, if desired (Koopman and Harvey, 2003); of course, these methods provide recursive formulas rather than explicit algebraic formulas. Thus, the state space approach cannot reveal certain fundamental properties of the signal extraction filters that are obvious from the matrix formulas; see Section 4.1 and 4.2. In addition, the matrix approach readily provides the full covariance matrix of the signal error, a quantity that is useful in certain applications; see Findley, McElroy, and Wills (2004). Hence, there is both need and appeal for having explicit, readily implemented matrix formulas for nonstationary signal extraction. Note also that one of the original motivations for the matrix approach to signal extraction of Bell and Hillmer (1988), was to provide a method of signal extraction for models that could not be put into state space form, e.g., long memory models. Although our results are presented in the ARIMA-model based framework, generalizations to long memory or heteroscedastic models are discussed as well.

We first present background material on signal extraction. The main theoretical results are in Section 2. Section 3 extends these results to estimating an unobserved signal at future times. Some applications of the matrix formulas are provided in Section 4. Examples of optimal finite sample seasonal adjustment and trend filters, along with their gain functions, are discussed in Section 5. Derivations of the basic formulas are contained in the appendix.

## 2 Matrix Formulas

Consider a nonstationary time series $Y_t$ that can be written as the sum of two possibly nonstationary components $S_t$ and $N_t$, the signal and the noise:

$$Y_t = S_t + N_t$$  \hspace{1cm} (1)
Following Bell (1984), we let $Y_t$ be an integrated process such that $W_t = \delta(B)Y_t$ is weakly stationary. Here $B$ is the backshift operator and $\delta(z)$ is a polynomial with all roots located on the unit circle of the complex plane (also, $\delta(0) = 1$ by convention). This $\delta(z)$ is referred to as the differencing operator of the series, and we assume it can be factored into relatively prime polynomials $\delta^S(z)$ and $\delta^N(z)$ (i.e., polynomials with no common zeroes), such that the series

$$U_t = \delta^S(B)S_t \quad V_t = \delta^N(B)N_t$$

(2)

are mean zero weakly stationary time series, which are uncorrelated with one another. Note that $\delta^S = 1$ and/or $\delta^N = 1$ are included as special cases. (In these cases either the signal or the noise or both are stationary.) We let $d$ be the order of $\delta$, and $d_S$ and $d_N$ are the orders of $\delta^S$ and $\delta^N$; since the latter operators are relatively prime, $\delta = \delta^S \cdot \delta^N$ and $d = d_S + d_N$.

There are many examples from econometrics and engineering that conform to this scheme. In the context of component estimation for seasonal time series, for example, the data typically consist of seasonal, trend, and irregular components (Gómez and Maravall, 2001):

$$Y_t = S_t + T_t + I_t.$$  

(3)

Alternatively, a cycle component (Durbin and Koopman, 2001) is included as well:

$$Y_t = S_t + T_t + C_t + I_t.$$  

(4)

Now although there are three or four unobserved components, we can always rewrite the models in terms of two components (signal and noise). For example, if we are interested in seasonally adjusting the series, we identify the seasonal component with the noise and the sum of the remaining components becomes the signal of interest. That is, $N_t = S_t$ and $S_t = T_t + I_t$ or $S_t = T_t + C_t + I_t$, depending on whether (3) or (4) holds respectively. Typically, the seasonal component is nonstationary with $\delta^N(z) = 1 + z + z^2 + \cdots + z^{11}$ for monthly data, and the trend is nonstationary as well. For a twice-integrated trend (and assuming that the irregular and cycle are stationary, which is usually the case) $\delta^S(z) = (1 - z)^2$. If instead we assume (4) (with the same ARIMA component models) and are interested in estimating the business cycle, then $S_t = C_t$ and $N_t = S_t + T_t + I_t$; in this case $\delta_S(z) = 1$ and $\delta_N(z) = (1 - z)(1 - z^{12})$. In this fashion, any number of multiple unobserved components can be reduced to two components, where the signal is defined as the sum of those components that are of interest, and the noise consists of the rest. We will see below in Section 5.2 that one can apply the matrix formulas for signal extraction without having to derive new ARIMA models for each separate combination of components. It shares this property with the Wiener-Kolmogorov approach of SEATS, which only requires a partitioning of the autocovariance generating function for the observed series.
As in Bell and Hillmer (1988), we assume Assumption A of Bell (1984) holds for the component decomposition, and we treat the case of a finite sample with \( t = 1, 2, \ldots, n \) for \( n > d \). Assumption A states that the initial \( d \) values of \( Y_t \), i.e., the variables \( Y = (Y_1, Y_2, \ldots, Y_d) \), are independent of \( \{U_t\} \) and \( \{V_t\} \). For a discussion of the implications of this assumption, see Bell (1984) and Bell and Hillmer (1988); in particular Bell (1984) discusses how the initial values for both the signal and noise components may be generated such that Assumption A holds. Note that mean square optimal signal extraction filters derived under Assumption A agree exactly with the filters implicitly used by a properly initialized state space smoother, see Bell and Hillmer (1991, 1992). A further assumption made is that \( \{U_t\} \) and \( \{V_t\} \) are uncorrelated with one another.

Now we can write (2) in a matrix form, as follows. Let \( \Delta \) be a \((n - d) \times n\) matrix with entries given by \( \Delta_{ij} = \delta_{i-j+d} \) (with the convention that \( \delta_k = 0 \) if \( k < 0 \) or \( k > d \)). The analogously defined matrices \( \Delta_S \) and \( \Delta_N \) have entries given by the coefficients of \( \delta^S(z) \) and \( \delta^N(z) \), but are \((n - d_S) \times n\) and \((n - d_N) \times n\) dimensional respectively. This means that each row of these matrices consists of the coefficients of the corresponding differencing polynomial, horizontally shifted in an appropriate fashion. Hence

\[
W = \Delta Y \quad U = \Delta_S S \quad V = \Delta_N N
\]

where \( Y \) is the transpose of \((Y_1, Y_2, \ldots, Y_n)\), and \( W, U, V, S, \) and \( N \) are analogously defined. We will denote the transpose of \( Y \) by \( Y' \). To express

\[
W_t = \delta^N(B)U_t + \delta^S(B)V_t
\]

in matrix form we need to define further differencing matrices \( \Delta_N \) and \( \Delta_S \) with row entries \( \delta^N_{i-j+d_N} \) and \( \delta^S_{i-j+d_S} \) given by the coefficients of \( \delta^N(z) \) and \( \delta^S(z) \) respectively, which are \((n - d) \times (n - d_S)\) and \((n - d) \times (n - d_N)\) dimensional. It follows from Lemma 1 of McElroy and Sutcliffe (2006) that

\[
\Delta = \Delta_N \Delta_S = \Delta_S \Delta_N.
\]

Then we can write down the matrix version of (5):

\[
W = \Delta_N U + \Delta_S V
\]

For each \( 1 \leq t \leq n \), the minimum mean squared error signal extraction estimate is \( \hat{S}_t = \mathbb{E}[S_t | Y] \). This can be expressed as a certain linear function of the data vector \( Y \) when the data are Gaussian. This estimate is also the minimum mean squared error linear estimate when the data is non-Gaussian. For the remainder of the paper, we do not assume Gaussianity, and by optimality we always refer to the minimum mean squared error linear estimate. Writing \( \hat{S} = (\hat{S}_1, \hat{S}_2, \ldots, \hat{S}_n)' \), the coefficients of these linear functions form the rows of a matrix \( F \):

\[
\hat{S} = FY
\]
The last row of \( F \), for example, corresponds to the concurrent filter, i.e., the one-sided filter used to extract a signal at “time present.” Due to symmetry properties of \( F \) (discussed in Section 4.1 below), this concurrent filter is the reverse of the first row of \( F \).

For any random vector \( X \), let \( \Sigma_X \) denote its covariance matrix. If the process \( \{X_t\} \) is weakly stationary, then the covariance matrix \( \Sigma_X \) is symmetric Toeplitz, i.e., the \( ij \)th entry only depends on \( i - j \). With this notation, we can now state the signal extraction formulas.

**Theorem 1** Suppose that Assumption A holds for the model decomposition (1), that \( \delta^N \) and \( \delta^S \) share no common zeroes, and that \( \{U_t\} \) and \( \{V_t\} \) are mean zero weakly stationary, uncorrelated with one another, and purely nondeterministic. Then the minimum mean square error linear estimate of \( S \) is given by \( \hat{S} = FY \), where

\[
F = \left( \Delta_S \Sigma_U^{-1} \Delta_S + \Delta_N \Sigma_V^{-1} \Delta_N \right)^{-1} \Delta_N \Sigma_V^{-1} \Delta_N. \tag{8}
\]

The covariance matrix of \( \hat{S} - S \) is given by \( M^{-1} \), where

\[
M = \Delta_S \Sigma_U^{-1} \Delta_S + \Delta_N \Sigma_V^{-1} \Delta_N. \tag{9}
\]

It also follows from our assumptions that all matrix inverses exist.

**Remark 1** When the signal is stationary these formulas reduce to (so \( \Delta_N = \Delta_N = \Delta \))

\[
F = \Sigma_S \Delta \Sigma_W^{-1} \Delta
M^{-1} = \Sigma_S - \Sigma_S \Delta \Sigma_W^{-1} \Delta \Sigma_S
\]

(cf. Bell and Hillmer (1988) and Bell (2004)). Likewise, when the noise is stationary we have

\[
F = \Sigma_N \Delta \Sigma_W^{-1} \Delta
M^{-1} = \Sigma_N - \Sigma_N \Delta \Sigma_W^{-1} \Delta \Sigma_N
\]

and \( \Delta_S = \Delta_S = \Delta \). These formulas are proved by simply manipulating (8) and (9), using the fact that

\[
(1 + \Sigma_S \Delta \Sigma_V^{-1} \Delta)^{-1} = 1 - \Sigma_S \Delta \Sigma_V^{-1} \Delta.
\]

**Remark 2** The assumption that \( \{U_t\} \) and \( \{V_t\} \) are weakly stationary in Theorem 1 can be relaxed somewhat. In order to implement (8) and (9) it is not necessary that \( \Sigma_U \) and \( \Sigma_V \) be Toeplitz, only invertible. For example, Nguyen, Bell, and Gomish (2004) discuss models for a sampling error component with variances that evolve over time, yielding a non-Toeplitz covariance matrix. In particular, suppose that the noise is a sampling error component given by \( N_t = h_t e_t \), where \( h_t \) is a positive deterministic quantity that generates a heteroscedastic effect, and \( e_t \) is a stationary time
series, e.g., an AR(2). Then we can write \( \Sigma_N = D(h) \Sigma_e D(h) \), where \( D(h) \) denotes a diagonal matrix with entries given by \( h_1, h_2, \ldots, h_n \), and \( \Sigma_e \) is the Toeplitz covariance matrix of \( \{e_t\} \). Then \( \Sigma_N \) is invertible, with inverse given by

\[
\Sigma_N^{-1} = D(h)^{-1} \Sigma_e^{-1} D(h)^{-1}.
\]

Bell (2004) also discusses seasonal heteroscedasticity models, where the differenced seasonal component has a non-Toeplitz covariance matrix. Theorem 1 still applies in these sorts of situations.

Since the matrices in \( M \) are roughly of dimension equal to the sample size, their inversion will not be overly burdensome. More precisely, the computation of \( \Sigma_U^{-1} \) involves the inversion of a \((n - d_S)\)-dimensional matrix; when \( \{U_t\} \) is stationary, the Toeplitz structure of \( \Sigma_U \) can be utilized so that its inversion requires order \( n^2 \) operations – see Golub and Van Loan (1996). Then to find a particular entry of \( M^{-1} \), we can use the LU decomposition (Golub and Van Loan (1996), p.121), obtaining the result in \( O(n^2) \) operations. Hence, the error covariance matrix \( M^{-1} \) can be computed fairly quickly, and the procedure is easy to implement on a computer (see the discussion in Section 5.1). In contrast, a state space approach will usually be faster (as will be the implementation of the Wiener-Kolmogorov filter in \( SEATS \)), which is important for large sample sizes (see de Jong and MacKinnon (1988) and Durbin and Quenneville (1997) for details). The main advantage in the matrix approach lies in the ease of implementation.

Note that if we have any new “signal” defined by \( HS \), where \( H \) is a \( 1 \times n \) dimensional matrix, then it will be estimated by the matrix \( HF \), and will have error covariance matrix \( HM^{-1}H' \). This calculation will potentially involve all the entries of \( M^{-1} \), not just the near-diagonal entries that state space smoothing algorithms are capable of producing. Applications that require a full knowledge of \( M^{-1} \) are benchmarking (Durbin and Quenneville, 1997), revision statistics, growth rates, and signal extraction diagnostics (Findley, McElroy, and Wills, 2004).

## 3 Component Forecasts

We now present an extension of these matrix formulas to the forecasting of an unobserved component. More precisely, suppose that it is desired to estimate some future values of the signal, denoted by \( S_f = (S_{n+1}, \ldots, S_{n+h})' \) (the \( f \) subscript denotes the “future”), but as before only the data \( Y = (Y_1, \ldots, Y_n)' \) are available. As a related problem, we first consider the linear projection of \( S_f \) onto \( S = (S_1, \ldots, S_n)' \), following Bell (2004). The optimal (as always, this signifies the minimum mean squared error among linear estimates) estimate is given by

\[
\hat{S}_f = DS.
\]
Here $D$ is the $h \times n$ matrix defined by (11) below. We arrive at the formula for $D$ through the following discussion, which introduces some notation that we need for Theorem 2. As in Bell (2004), we first consider the equation

$$\tilde{\Delta}_S \begin{bmatrix} S_p \\ S_f \end{bmatrix} = \begin{bmatrix} S_p \\ U_f \end{bmatrix},$$

where $S_p = (S_{n+1-d_S}, \ldots, S_n)'$ and $U_f = (U_{n+1}, \ldots, U_{n+h})'$ (here the $p$ subscript refers to the “present”). The matrix $\tilde{\Delta}_S$ is a lower triangular matrix defined by

$$\tilde{\Delta}_S = \begin{bmatrix} 1_{d_S} \\ \Delta_S \end{bmatrix},$$

where $\Delta_S$ is $h \times (d_S + h)$ dimensional. Thus $\tilde{\Delta}_S$ is square of dimension $d_S + h$, and is invertible (because it is unit lower-triangular). Next we compute the optimal estimate of $U_f$ given $U$, which will be denoted by $\hat{U}_f$. Let the covariance matrix of $(U', U_f')$ be subdivided into four portions:

$$\Sigma_{(U,U_f)} = \begin{bmatrix} \Sigma_U & \Sigma_{UU_f} \\ \Sigma_{U_f} & \Sigma_{U_f} \end{bmatrix},$$

where $\Sigma_{UU_f}$ denotes $E[UU_f']$, and so forth. Then $\hat{U}_f$ is given by (cf. formula (12.28) of Bell (2004))

$$\hat{U}_f = \Sigma_{U_f}^{-1} U.$$

So we define the matrix $D$ by the formula

$$D = [0_{h \times d_S} \ 1_h] \tilde{\Delta}_S^{-1} \begin{bmatrix} 0_{d_S \times (n-d_S)} \\ \Sigma_{U_f} \Sigma_{U_f}^{-1} \Delta_S \end{bmatrix}.$$

(11)

This is a simple matrix approach to forecasting nonstationary processes. With this notation, we can state the main theorem for estimating future values of an unobserved component.

**Theorem 2** Suppose that Assumption A holds for the model decomposition (1), that $\delta^N$ and $\delta^S$ share no common zeroes, and that $\{U_t\}$ and $\{V_t\}$ are mean zero weakly stationary, uncorrelated with one another, and purely nondeterministic. Then the minimum mean square error linear estimate of $S_f$ given $Y$ is $\hat{S}_f = DFY$, where $F$ is given by (8) and $D$ is given by (11). In addition,

$$\begin{bmatrix} \hat{S} \\ \hat{S}_f \end{bmatrix} = \begin{bmatrix} 1_n \\ D \end{bmatrix} FY$$

has error covariance matrix

$$\begin{bmatrix} 1_n \\ D \end{bmatrix} M^{-1} \begin{bmatrix} 1_n D' \\ 0 \\ 0 \end{bmatrix} G$$

where $G$ is the covariance matrix of $DS - S_f$, which is given in (20) below.
Remark 3 Similar approaches can yield backcast formulas, as well as estimates of unobserved components at time points where some of the observed data is missing. For the backcasting case, it is convenient to place the initial values at the end of the series and reverse the discussion. For both of these problems, the derivation is quite a bit more complicated.

The method of Theorem 2 allows for the forecasting of future values of an estimated signal. For example, if one is interested in future values of an unobserved trend or cycle or nonseasonal component, its optimal forecasts can be estimated in this way. A quite particular application comes from the literature on growth rates, where the growth rate over an interval $p$ of a signal of interest is defined by $S_{t+p} - S_{t-p}$, for example. This can be considered a “centered” measure of the rate of growth of the signal at time $t$ (whereas $S_t - S_{t-p}$ would be an off-center measure of the growth rate of the signal at time $t$). In the econometrics literature, interest often focuses on growth rates at the concurrent time point $n$, in which case the quantity of interest is $S_{n+p} - S_{n-p}$, where data up to time $n$ is available. This would be estimated (setting $h = p$) via

$$
\hat{S}_{n+p} - \hat{S}_{n-p} = (e_{n+p} - e_{n-p})' \begin{bmatrix} 1_n \\ D \end{bmatrix} FY
$$

where $e_j$ is the vector with $j$th coordinate 1 and 0 elsewhere. The error covariance matrix is easily obtained from this formula.

4 Theoretical Applications of (8)

The matrix formula (8) shows us, writing $F = Q\Delta_N$ for $Q = M^{-1}\Delta_N \Sigma_V^{-1}$, that filtering with $F$ first involves applying the noise differencing matrix $\Delta_N$ to the data $Y$. This reduces the noise component $N$ to stationarity, but the signal will not be transformed to stationarity, since no zeroes of $\delta^S$ are shared by $\delta^N$. It is intuitive that the signal extraction filters for every time point $t$ involve differencing the noise component and passing the signal component; of course, the signal is altered by the filtering, but its nonstationarity is preserved. Below, some concrete applications of the matrix approach are given.

4.1 Symmetry Properties

When $\{U_t\}$ and $\{V_t\}$ are weakly stationary, both $F$ and $M^{-1}$ have an interesting symmetry property; namely, the $i$th row is the reverse of row $n-i+1$. Define the transverse transpose of a square matrix to be the matrix obtained by flipping the entries about the diagonal running from lower left to upper right. For any $n$-dimensional square matrix $A$, this transverse transpose is given by $A^*_ij = A_{n-j+1,n-i+1}$. It is easy to show that (i) $(AB)^* = B^* A^*$ and (ii) $(A^{-1})^* = (A^*)^{-1}$. Then
the above symmetry property is simply the statement that $F^* = F'$ (and similarly for $M^{-1}$). But this is easily verified using the above two properties of transverse transpose, along with

$$
\left( \Delta_N^\prime \Sigma_V^{-1} \Delta_N \right)^* = \Delta_N^\prime \Sigma_V^{-1} \Delta_N
$$

(12)

(and similarly for $\Delta_S^\prime \Sigma_U^{-1} \Delta_S$). This identity (12) relies on the special properties of the matrices $\Delta_N$. Consider the $n \times n$ matrix $\tilde{\Delta}_N$ with entry $ij$ given by $\delta_N^{ij}$, so that $[0 \quad (n-d_N) \times d_N] \tilde{\Delta}_N = \Delta_N$. The dimension subscripts will be left off for brevity. Now $\tilde{\Delta}_N$ is Toeplitz, and note that $A^* = A$ for any Toeplitz matrix (as mentioned in Remark 2 above, (8) may hold when $\Sigma_U$ and $\Sigma_V$ are not Toeplitz, and in this case the above symmetry properties of $F$ and $M^{-1}$ need not be true). We can write

$$\Delta_N^\prime \Sigma_V^{-1} \Delta_N = \tilde{\Delta}_N^\prime \left[ \begin{array}{ccc} 0 & 0 \\ 0 & \Sigma_V^{-1} \end{array} \right] \tilde{\Delta}_N.$$

Applying the $*$ operator yields

$$\left( \Delta_N^\prime \Sigma_V^{-1} \Delta_N \right)^* = \tilde{\Delta}_N^\prime \left[ \begin{array}{ccc} \Sigma_V^{-1}^* & 0 \\ 0 & 0 \end{array} \right] (\tilde{\Delta}_N^\prime)^* = \Delta_N^\prime \Sigma_V^{-1} \Delta_N,$$

where in the last equality we have used the properties (i) and (ii) above, and the easily verified property that $[1 \quad 0] \tilde{\Delta}_N^\prime = \Delta_N$. This verifies (12).

It follows that if $n$ is odd, the “central” filter for row $(n+1)/2$ is a reverse of itself, which implies that it is symmetric. Also since $M^{-1}$ is the covariance matrix of the signal extraction errors, it follows from (9) that the mean squared errors (which are the diagonal entries of $M^{-1}$) have the symmetry property $\mathbb{E}(\hat{S}_t - S_t)^2 = \mathbb{E}(\hat{S}_{n-t+1} - S_{n-t+1})^2$ for each $t$ (see Figures 2 and 6). It is not clear that these symmetry properties can be easily obtained from state space algorithms.

### 4.2 Fundamental Zeros of the Filter Transfer Functions

The formula (8) for the signal extraction filter matrix $F$ allows us to derive some important properties in the frequency domain. The $l$th row of $F$ contains the coefficients of the filter that produces $\hat{S}_l$. The frequency response function of this filter is

$$H_l(\lambda) = \sum_{j=1}^n F_{lj} e^{-i(l-j)\lambda} = e^{-il\lambda} \sum_{j=1}^n F_{lj} e^{ij\lambda}$$

(13)

for $\lambda \in [-\pi, \pi]$ and $i = \sqrt{-1}$ (see Pollock, 1999). From $H_l$, one can easily obtain the gain $G_l(\lambda) = |H_l(\lambda)|$ and phase function $\phi_l(\lambda) = \tan^{-1}(\text{Im}H_l(\lambda)/\text{Re}H_l(\lambda))$, which is well-defined when $H_l(\lambda) \neq 0$ (see Findley and Martin, 2006) for a similar treatment). Writing $F = Q\Delta_N$ as above, we have

$$H_l(\lambda) = \sum_{k=1}^n Q_{lk} \sum_{j=1}^n \delta_{k-j+d_N}^{N} e^{i(j-l)\lambda} = e^{-il\lambda} \sum_{k=1}^n Q_{lk} e^{ik\lambda} \delta_{N}^{N} (e^{-i\lambda}).$$
In other words, the frequency response for row $l$ of $F$ is given by the product of the frequency responses for $\delta^N(z)$ and row $l$ of $Q$. Hence $G_l$ is given by the product of the gain functions for $\delta^N(z)$ and row $l$ of $Q$, and $\phi_l$ is given by the sum of the corresponding phase functions. In this manner, Appendix D of Findley and Martin (2006) computes continuous phase and phase delay functions for model-based concurrent seasonal adjustment and trend filters. In the examples that Findley and Martin (2006) consider, the phase function for $\delta^N(e^{-i\lambda})$ is simple to write down, and can be continuously defined at the noise frequencies corresponding to the zeroes of $\delta^N(z)$ on the unit circle. The phase function for row $l$ of $Q$ is well-defined everywhere for many examples, and hence can be separately calculated and added to the phase function of $\delta^N(e^{-i\lambda})$, yielding a continuous phase function at all frequencies.

The calculations required to produce the phase functions of Findley and Martin (2006) depend on knowing $Q$ in the product $F = Q\Delta_N$. But $Q$ cannot be obtained from the other approaches discussed in this paper. That is, neither the state space approach nor the method of SEATS (i.e., application of the method of Tunnicliffe-Wilson to obtain the same filter as that of the bi-infinite sample Wiener-Kolmogorov signal extraction filter applied to data extended by forecasts and backcasts) can produce the matrix $Q$.

5 Empirical Illustrations

5.1 A Note on Efficient Computation of $F$ and $M$

An alternative “square root information” approach to the formulas for $F$ and $M^{-1}$ is given here, which has certain computational advantages. Let $T_U = \Sigma_U^{-1/2}$ and $T_V = \Sigma_V^{-1/2}$ be square matrices obtained from Cholesky decompositions of $\Sigma_U^{-1}$ and $\Sigma_V^{-1}$ respectively. Then define the $2n-(d_U+d_V)$ by $2n$-dimensional matrix $T$ by

$$T = \begin{bmatrix} T_U \Delta_S & 0 \\ -T_V \Delta_N & T_V \Delta_N \end{bmatrix},$$

for which $T[S'Y']$ consists of linear combinations of $U$ and $V$. Next, form the $QR$ decomposition of $T$ (Golub and Van Loan, 1996), where $Q$ is square and orthonormal, and $R$ is upper triangular. Writing $R$ in block form, we have

$$R = \begin{bmatrix} R_{11} & R_{12} \\ 0 & R_{22} \end{bmatrix}.$$ 

Then it is easy to show that $F = -R_{11}^{-1}R_{12}$ and $M = R_{11}R_{11}$. Since $R_{11}$ is upper triangular, both $F$ and $M^{-1}$ can be speedily computed once $R$ is determined. The matrices $T_U$ and $T_V$ are readily determined (e.g., use of the Durbin-Levinson algorithm – Brockwell and Davis, 1991). The $QR$
decomposition takes about \( n^3 \) operations, and is quite stable numerically. Thus for computational purposes, this approach is to be recommended (an alternative proof of Theorem 1 can also be derived). In summary, the procedure is:

1. Obtain \( T_U \) and \( T_V \)
2. Construct \( T \)
3. Get \( R \) from the \( QR \) decomposition of \( T \)
4. Set \( F = -R_{11}^{-1} R_{12} \) and \( M = R_{11}' R_{11} \).

This approach can also be generalized to handle forecasting and backcasting.

5.2 Estimating Component Models

In order to implement the results of Theorem 1, it is necessary to obtain the component models for \( S_t \) and \( N_t \) from the data. Together with (2), specifying ARMA models for \( U_t \) and \( V_t \) will fully specify an ARIMA model for \( S_t \) and \( N_t \). In the structural approach of Harvey (1989), the ARMA model for \( W_t \) is determined by the component models. The Gaussian likelihood for \( W_t \) depends directly on \( \Sigma_W \), which in turn depends on the ARMA models for \( U_t \) and \( V_t \). Therefore maximization of the likelihood provides estimates of the ARMA parameters for both \( U_t \) and \( V_t \). This approach differs from the canonical decomposition technique of Hillmer and Tiao (1982), where an ARMA model for \( W_t \) is specified first; one estimates the ARMA parameters for \( W_t \), and then one tries to decompose the model for \( W_t \) into component models, using (5).

Of course, the specification of component models is simply a basic requirement of model-based signal extraction. Oftentimes, however, the observed data is modeled as the sum of several (i.e., more than two) unobserved ARIMA components, and the signal and noise components actually consist of a partition of these various unobserved components; recall the examples (3) and (4) of Section 2. At first, it seems that one would have to determine ARIMA models for \( S_t \) and \( N_t \) from all the various ARIMA models for the unobserved components – a procedure that requires spectral factorization (Hillmer and Tiao (1982) and Burman (1980)) and a substantial amount of programming. However, the actual component models are not needed; rather only their autocovariance generating functions are required. In \( SEATS \) one can obtain the Wiener-Kolmogorov signal extraction filter directly from a knowledge of the component models, and one need not determine an exact ARIMA model for signal and noise (though \( SEATS \) does this for informational purposes). Similarly in the matrix approach, we see that (8) only depends on the autocovariances of signal and noise, and these can be quickly obtained directly from the ARIMA models for the unobserved components, thus circumventing the need to obtain ARIMA models for \( S_t \) and \( N_t \). We illustrate this through an example.
Consider the unobserved components model (4) of Section 2, and suppose our signal of interest is the cycle. For concreteness, suppose that the component models are given by

\[ \phi(B)C_t = \theta_C(B)\epsilon_t^C \]
\[ (1 + B + \cdots + B^{11})S_t = \theta_S(B)\epsilon_t^S \]
\[ (1 - B)^2T_t = \theta_T(B)\epsilon_t^T \]

where the irregular \( I_t \) is white noise, and all the \( \epsilon_t \) sequences are white noise sequences (that are independent of each other). Since \( C_t \) is the signal, the noise is

\[ N_t = S_t + T_t + I_t. \]

The ARIMA model for the noise is determined by multiplying all differencing polynomials from its constituent parts, and applying this product to \( N_t \). Then its MA polynomial is determined through algebra and spectral factorization techniques:

\[ (1 - B)(1 - B^{12})N_t = (1 - B)^2\theta_S(B)\epsilon_t^S + (1 + B + \cdots + B^{11})\theta_T(B)\epsilon_t^T + (1 - B)(1 - B^{12})I_t \]

The right hand side can be re-expressed, using spectral factorization techniques, as a single MA process, written as \( \theta_N(B)\epsilon_t^N \). Now in order to avoid the labor of spectral factorization, observe that we only need to know the autocovariances of \( V_t = (1 - B)(1 - B^{12})N_t \), not the entire ARIMA model for \( N_t \). Re-expressing (14) in matrix form yields the equations

\[ V = \Delta N = \Delta T G + \Delta S H + \Delta N I \]
\[ G = \Delta S S \]
\[ H = \Delta T T. \]

Here the differencing matrices are defined in a fashion similar to those in Section 2. Now since the vectors \( G, H, \) and \( I \) are uncorrelated with each other by assumption, we obtain

\[ \Sigma_V = \Delta_T \Sigma_G \Delta_T' + \Delta_S \Sigma_H \Delta_S' + \Delta \Sigma T \Delta_T'. \]

Of course since \( G_t = \theta_S(B)\epsilon_t^S \) and \( H_t = \theta_T(B)\epsilon_t^T \), their autocovariances are easily obtained by standard algorithms (see Tunnicliffe-Wilson, 1979). In this way \( \Sigma_V \) is determined. This provides a flexible procedure, because if we now are interested in another signal, we can construct a new \( F \) from only a knowledge of the autocovariances of the differenced unobserved components.

More generally, suppose the noise (though the same argument applies to the signal) can be expressed as the sum of \( m \) unobserved components \( \epsilon_t^{(i)} \) for \( 1 \leq i \leq m \). Suppose that each of these
The seasonal differencing operator is
\[ \delta^{(i)} \text{ operator} = (1 + B + \cdots + B^{11}) \], where \( \delta^{(i)}(z) \) is a differencing polynomial and the \( \nu^{(i)} \)'s are mean zero weakly stationary processes that are uncorrelated with one another. If we know the autocovariance matrix \( \Sigma_{\nu^{(i)}} \) of \( \nu^{(i)} \) and there is no \( z \) such that \( \delta^{(i)}(z) = 0 \) for all \( i \), then we can construct the covariance matrix for the differenced noise as follows. Let \( \delta^{(i)}(z) = \Pi_{j \neq i} \delta^{(j)}(z) \); then we have

\[ V_t = \Pi_{j=1}^n \delta^{(j)}(B) \eta_t = \sum_{i=1}^m \delta^{(i)}(B) \nu^{(i)}_t. \] (15)

Then, letting \( \Delta^{(i)} \) be defined as previous differencing matrices but with row entries given by \( \delta^{(i)} \), we have

\[ \Sigma_V = \sum_{i=1}^m \Delta^{(i)} \Sigma_{\nu^{(i)}} \Delta^{(i)\prime}. \] (16)

The condition that there is no common zero among the \( \delta^{(i)}(z) \) polynomials ensures that \( \Sigma_V \) is invertible. Imposing this condition is not restrictive, since the presence of such common factors could be canceled out of the equation (15). If any of the \( m \) components are stationary, then the corresponding \( \delta^{(i)}(z) = 1 \).

5.3 Examples

We now describe some examples of the application of formula (8). Consider the series of U.S. Retail Sales of Shoe Stores data from the monthly Retail Trade Survey, from 1984 to 1998 (so \( n = 170 \)). The logarithms of the series can be modeled with an airline model (Brockwell and Davis, 1991). Then applying (3) to the logged time series \( Y_t \), we can obtain estimated component models for seasonal \( S_t \), trend \( T_t \), and irregular \( I_t \) given as follows:

\[ (1 - B)(1 - B^{12})Y_t = (1 - .57B)(1 - .34B^{12}) \epsilon_t^Y, \quad \sigma^2_{\epsilon_t^Y} = .00096 \]
\[ r(B)S_t = (1 + 1.11B + .96B^2 + .74B^3 + .47B^4 + 20B^5 - .03B^6 - .23B^7 - .36B^8 - 47B^9 - .51B^{10} - .68B^{11}) \epsilon_t^S, \quad \sigma^2_{\epsilon_t^S} = .000093 \]
\[ (1 - B)^2 T_t = (1 + .09B - .91B^2) \epsilon_t^T, \quad \sigma^2_{\epsilon_t^T} = .000018 \]
\[ \sigma^2_T = .00026 \]

Here the seasonal differencing operator is \( r(B) = 1 + B + \cdots + B^{11} \), and the trend differencing operator is \( (1 - B)^2 \). The \( \epsilon_t \) sequences are white noise innovation series. The parameters for the data model were found via maximum likelihood, and the component models were found via the canonical decomposition (Hillmer and Tiao, 1982). If we wish to seasonally adjust the data, the noise is the seasonal \( S_t \) and the signal is the trend-irregular \( T_t + I_t \); hence the signal differencing operator is \( \delta^S(B) = (1 - B)^2 \), and the noise differencing operator is \( r(B) \). Then the corresponding differencing matrices are denoted by \( \Delta_T \) and \( \Delta_S \) respectively. The covariance matrices for differenced signal and noise are \( \Sigma_{\Delta_T(T+I)} \) and \( \Sigma_{\Delta_S S} \) respectively, which can be computed from (17)
directly. In particular, letting $G = \Delta_T T$, we have from (16) $\Sigma_{\Delta_T (T+I)} = \Sigma_G + \Delta_T \Sigma_T \Delta_T'$. The signal extraction matrix is given by

$$F = \left( \Delta_T' \Sigma_{\Delta_T (T+I)}^{-1} \Delta_T + \Delta_S' \Sigma_{\Delta_S}^{-1} \Delta_S \right)^{-1} \Delta_S' \Sigma_{\Delta_S}^{-1} \Delta_S,$$

where all autocovariances can be obtained from (17) via algorithms in Tunnicliffe-Wilson (1979).

In Figure 1 we plot the logged series together with the estimated seasonally adjusted data. The seasonal adjustment is enclosed by confidence bands, given by plus and minus twice the square root of the mean squared error at each time point. Figure 2 displays the mean squared error curve by itself; note the increased error at the beginning and end of the series. Next, Figure 3 displays seasonal adjustment filters for three time points: $t = 86$ (denoted by “Central”), $t = 158$ (denoted by “Preliminary”), and $t = 170$ (denoted by “Concurrent”). Now by applying the material from Section 4.2, the squared gain of the filter at row $h$ is given by

$$G^2_l(\lambda) = \left( \sum_{j=1}^{n} F_{lj} \cos(j\lambda) \right)^2 + \left( \sum_{j=1}^{n} F_{lj} \sin(j\lambda) \right)^2.$$

Plots of the squared gains over $[0, \pi]$ for the Central, Preliminary, and Concurrent filters are given in Figure 4. For a discussion of the gain and phase properties of finite-sample signal extraction filters, see Findley and Martin (2006). As Section 4.2 establishes, the squared gains are zero at the zeroes of $r(e^{i\lambda})$, which for $\lambda \geq 0$ are at $2\pi k/12$ for $k = 1, 2, \cdots, 6$. Thus the filters suppress variance components with periods of 12, 6, 4, 3, 2, and 2 months.

As a second example we consider the same series, but now our signal of interest is the trend $T_t$, so that the noise is the seasonal-irregular $S_t + I_t$. If we wish to estimate the trend the signal differencing operator is $(1 - B)^2$ and the noise differencing operator is $r(B)$. Then the corresponding differencing matrices are denoted by $\Delta_T$ and $\Delta_S$ respectively. The covariance matrices for differenced signal and noise are $\Sigma_{\Delta_T T}$ and $\Sigma_{\Delta_S (S+I)}$ respectively, which can be computed from (17). Indeed, letting $H = \Delta_S S$ and using (16) we have $\Sigma_{\Delta_S (S+I)} = \Sigma_H + \Delta_S \Sigma_T \Delta_T'$. The signal extraction matrix is given by

$$F = \left( \Delta_T' \Sigma_{\Delta_T (T+I)}^{-1} \Delta_T + \Delta_S' \Sigma_{\Delta_S}^{-1} \Delta_S \right)^{-1} \Delta_S' \Sigma_{\Delta_S}^{-1} \Delta_S,$$

where all autocovariances can be obtained from (17) via algorithms in Tunnicliffe-Wilson (1979). In Figure 5 we plot the logged series together with the trend estimate. This estimate is enclosed by confidence bands, given by plus and minus twice the square root of the mean squared error at each time point. Figure 6 displays the mean squared error curve alone. Next, Figure 7 displays Central, Preliminary, and Concurrent trend filters for three time points. As in the previous example, we can compute the squared gains, which are displayed in Figure 8.
In comparing Figures 1 and 5, observe that the trend estimate is much smoother than the seasonally adjusted; this is accounted for by the presence of the irregular component in the seasonally adjusted component. The symmetry of the mean squared errors is apparent from Figures 2 and 6. The up-turning of the mean squared error at the beginning and end of the sample is a well-known effect, and is essentially due to the increased error in estimating the signal at the boundary of the sample. In both Figures 3 and 7 we see that the filter coefficients contain negative spikes at seasonal lags, which effect the suppression of the seasonal component. The greater width of the central spike in the trend filters of Figure 7 allows for inclusion of the component and exclusion of the irregular. Finally, the squared gain plots of Figures 4 and 8 show the attenuation of seasonal frequencies; for the trend filters, this is combined with a low-pass filter effect. In comparing central, preliminary, and concurrent filters, there is some variation in trough width among the squared gain plots. For further study of such finite sample filters and their frequency domain properties, see Findley and Martin (2006).

Acknowledgements The author would like to thank David Findley for careful reading of this article, which led to substantial improvements; I also thank the referees for suggesting the “square root information” approach to computing $F$ and $M$ as well as many other improvements. This report is released to inform interested parties of research and to encourage discussion. The views expressed on statistical issues are those of the author and not necessarily those of the U.S. Census Bureau.

6 Appendix

Proof of Theorem 1. First note that all covariance matrices for $U$, $V$, and $W$ are invertible, because the stationary series $\{U_t\}$, $\{V_t\}$, and $\{W_t\}$ are assumed to be purely nondeterministic – see Proposition 5.1.1 of Brockwell and Davis (1991). Let $1_n$ denote the $n$-dimensional identity matrix, and let $F$ have the stated form (8). First we show that $M$ is invertible by showing that $Mx = 0$ implies that $x = 0$. If a vector $x$ were in the null space of $M$, then due to its symmetry and non-negative definiteness, $x$ would have to be in the null space of both $\Delta_S$ and $\Delta_N$. As demonstrated in Lemma 2 of McElroy and Sutcliffe (2006), $x$ must be zero because $\delta^S(z)$ and $\delta^N(z)$ have no common zero. Originally, we derived (8) from formulas of Bell and Hillmer (1988). Here, to save space we simply verify that $\hat{S}$ defined by (8) has the defining property of the optimal estimate, namely that the error process $\epsilon = \hat{S} - S$ is orthogonal to all linear combinations of the observations $Y$ (the original proof is in McElroy (2005)). Now

$$\epsilon = FY - S = (F - 1_n)S + FN = M^{-1}\Delta_N'\Sigma_V^{-1}V - M^{-1}\Delta_S'\Sigma_U^{-1}U,$$

(18)
and so is uncorrelated with the initial values $Y_*$ by Assumption A. In addition, by (7) and (6) we have
\[ E[\epsilon W'] = M^{-1} \Delta'_N \Sigma_v^{-1} \Sigma_v \Delta'_S - M^{-1} \Delta'_S \Sigma_U^{-1} \Sigma_U \Delta'_S = M^{-1} (\Delta - \Delta) = 0. \]
Since $Y$ can be expressed in terms of its initial values $Y_*$ and $W$ (see Bell (2004), for example), this shows that $\epsilon$ is orthogonal to any linear combination of $Y$. Moreover, we can use (18) to compute $E[\epsilon'] = M^{-1}$. Hence the theorem is proved. \[ \square \]

**Proof of Theorem 2.** We will work with the full estimated component $(\hat{S}', \hat{S}'_f)$. As in the proof of Theorem 1, it suffices to demonstrate that the error process is orthogonal to $Y$. Now from (18) and (10)
\[ \epsilon = \left[ \begin{array}{c} \hat{S} \\ \hat{S}_f \end{array} \right] - \left[ \begin{array}{c} S \\ S_f \end{array} \right] = \left[ \begin{array}{c} 1_n \\ D \end{array} \right] M^{-1} \Delta'_N \Sigma_v^{-1} V - \left[ \begin{array}{c} 1_n \\ D \end{array} \right] M^{-1} \Delta'_S \Sigma_U^{-1} U + \left[ \begin{array}{c} 0 \\ DS - S_f \end{array} \right]. \quad (19) \]
We next compute the error $DS - S_f$, using the partition
\[ \tilde{\Delta}^{-1}_S = \left[ \begin{array}{cc} 1_{d_s} & 0_{ds \times h} \\ A & B \end{array} \right]. \]
$B$ is a square matrix of dimension $h$ and lower triangular, with entries given by the coefficients of $1/\delta_S(z)$ (see Bell, 2004). Hence we have
\[ DS - S_f = [0_{h \times d_s} 1_h] \tilde{\Delta}^{-1}_S \left[ \begin{array}{c} S_p \\ \Sigma_U U \Sigma_U^{-1} \Delta S \\ S_f \end{array} \right] - \left[ \begin{array}{c} S_p \\ S_f \end{array} \right] \]
\[ = [0_{h \times d_s} 1_h] \tilde{\Delta}^{-1}_S \left[ \begin{array}{c} S_p \\ \tilde{\Delta}_S - \Delta S \\ S_f \end{array} \right] \\ = [A B] \left[ \begin{array}{c} S_p \\ \tilde{U}_f - S_f \end{array} \right] \]
\[ = [A B] \left[ \begin{array}{c} 0 \\ \tilde{U}_f - U_f \end{array} \right] \\ = B (\tilde{U}_f - U_f). \]
Note that if the initial values of $S$, say $S_*$, were assumed to be uncorrelated with $U$, then the above calculation shows that $DS$ is the optimal linear estimate of $S_f$. However, this assumption on $S_*$ is typically not true in our context, so we cannot conclude that $DS$ is an optimal estimate of $S_f$ given $S$. However, by Assumption A it is uncorrelated with both $Y_*$ and $W$, and thus $DS$ is an optimal estimate of $S_f$ given $Y$. Now (19) shows that each of the three terms is mutually orthogonal: as
in the proof of Theorem 1, \( W \) is orthogonal to the sum of the first two terms, and in addition \( W \) is orthogonal to \( DS - S_f \), since \( \hat{U}_f - U_f \) only depends on \( \{U_t\} \) and is orthogonal to \( U \). Thus \( W \) is uncorrelated with the error process. Finally, since \( \epsilon \) is a linear function of only \( U_t \) and \( V_t \), it is also uncorrelated with \( Y \) by Assumption A. Since the error process is orthogonal to \( Y \), the filter must be optimal.

For the mean squared error calculation, we compute \( \mathbb{E}[\epsilon' \epsilon] \). The only difficulty is computing the cross-covariance between the second and third terms of (19). But since \( DS - S_f = B(\hat{U}_f - U_f) \), we see that \( U \) is uncorrelated with \( DS - S_f \), so that the second and third terms of (19) are orthogonal. Hence the error covariance matrix has the stated form, with

\[
G = B \left( \Sigma_{U_f} - \Sigma_{U_f} \Sigma_{U_U}^{-1} \Sigma_{U_U} \right) B',
\]

utilizing (12.30) of Bell (2004). This concludes the proof. \( \square \)
